PEDIATRIC PAPILLARY THYROID CANCER

Growth pattern and metastatic behavior of papillary thyroid cancer are similar in prepubertal children and adolescents

SUMMARY

BACKGROUND
Although uncommon, thyroid cancer is not unusual in adolescents and in the young adult population. Between 1975 and 2000, thyroid cancer represented approximately 7.8% of all cancers diagnosed in the 15- to 19-year age group according to data in the Surveillance Epidemiology and End Results (SEER) database (1). The yearly incidence of differentiated thyroid cancer (papillary and follicular thyroid cancer) in the United States in patients from 5 to 20 years of age ranged from 0.7 to 1.4 cases per year per million in patients 5 to 20 years of age (SEER 1975 to 2000) (1). The objective of the study by Machens et al. was to provide comprehensive clinicopathologic data, comparing the growth pattern and metastatic behavior of papillary thyroid cancer between children and adolescents.

PATIENTS AND METHODS
A total of 83 consecutive patients 18 years of age or younger had surgery for papillary thyroid cancer (PTC) from November 1994 through December 2009. A total of 36 patients had initial surgery and 47 had reoperations for suspected or confirmed locoregional disease, mainly lymph-node metastases. Of the 83 patients, 57 (69%) were women and 26 (31%) were men, comprising 9% of the 921 patients treated at the Martin Luther University, Halle (Saale), Germany, for papillary thyroid cancer during this period.

Five (6%) of the 83 patients, 9, 12, 14, and 15, and 16 years of age, had a history of external radiation for inoperable intrathoracic neuroblastoma, nephroblastoma (Wilms’ tumor), Hodgkin’s lymphoma, acute lymphocytic leukemia, and medulloblastoma 5 to 10 years earlier.

All 83 patients had total thyroidectomy, 80 of whom (96%) also had systematic lymph-node dissection, and 57 (69%) had lateral neck compartment dissection. In addition, the upper anterior mediastinum was dissected in 7 (8%) of the 83 patients. Three children did not have lymph-node dissection because they were incidentally found to have 4-, 6-, and 10-mm solitary PTCs, confined to the thyroid gland.

RESULTS
Clinicopathologic Patient Characteristics by Age Groups and Tumor Growth Pattern (Figures 1 to 4)

Among the 83 patients with PTC, there were no age-related difference in sex distribution, reoperation rate, history of external radiation, multifocal tumor growth, number of thyroid cancers, extrathyroidal tumor growth, lymph-node metastases, number of involved and removed lymph-node metastases, number of involved and dissected lymph-node metastases, or distant metastases (Figure 1).

After stratifying the tumor growth pattern, patients with extra-thyroidal tumor growth were found to have larger tumors,
especially in the highest age group, but this difference was not significant (Figures 2 and 3).

When stratified by increments of 10 lymph nodes, significant relationships were found with the intensity of lymph-node metastases and multifocal tumor growth, the number of thyroid cancers, and extrathyroidal tumor growth. However, all other clinicopathologic variables, including patient age at first diagnosis, did not differ significantly when grouped by the number of lymph-node metastases (Figure 4).

CONCLUSION
This study suggests that there is a similar growth pattern and metastatic behavior of PTC in prepubertal children and adolescents.

COMMENTARY
Almost all the young patients in this study had lymph-node metastases and extrathyroidal tumor growth without a significant difference between prepubertal children and adolescents. The authors suggest that typically, children and adolescents with locoregional metastases trigger a workup for thyroid cancer and prompt referral for specialist surgical care, introducing referral and age bias in studies (2,3). The authors make the point that if children had more extensive disease as compared with adolescents, the children should have been overrepresented among the pediatric patients in this study, which apparently is not the case. However, this is a relatively small study that may not have been large enough to uncover minor age-related differences among the two study groups. The authors conclude that having comparable extent of disease, children should not receive less extensive neck surgery as compared with adolescents, which may result in a higher rate of locoregional recurrence in young children. A study of 19 patients by Robie et al. (3) found a strong trend toward locoregional recurrence among those with metastatic disease to more than five cervical nodes (P<0.08); however, the primary operations on the thyroid and regional nodes were not significant predictors of neck recurrence. Although there have been no deaths among these patients, 25% had persistent disease at a mean follow-up of 12.6 years, leading the authors to conclude that the incidence of surgical morbidity does increase with more extensive surgery, and that outcome is predicted primarily by the initial extent of disease. Likewise, Machens et al. also suggest that the extent of the initial operation is what influences locoregional recurrence rates rather than the child’s age; however, they provide the caveat that with surgery in children and adolescents, and especially in younger children, there is more of a risk than in older patients, and thus should be treated by dedicated surgical centers that have experience with pediatric neck surgery.

SEER Database Information on the Incidence Rates and Mortality Rates in Children and Adolescents, and Young Adults (Figures 5, 6, and 7)
A SEER monograph (1) of cancer epidemiology in older adolescents and young adults (15 to 29 years of age) provides important insight into the epidemiology of thyroid cancer in children. The SEER data show that in the United States, from 1975 through 2000, thyroid cancer accounted for about 10% of all malignancies diagnosed in individuals 15 to 29 years of age, and thyroid cancer was the fourth most common cancer in this age group. The incidence of thyroid cancer increased rapidly between 15 and 29 years of age, reaching a plateau by the 5th and 6th decades (Figure 5).

In 2000, the estimated incidence rates of thyroid cancer per million in persons younger than age 30 years were 0 for age
PEDIATRIC PAPILLARY THYROID CANCER

Machens A, et. al.

<5 years, 1.0 for ages 5 to 9, 4.3 for ages 10 to 14, 17.6 for ages 15 to 19, 43.3 for ages 20 to 24, and 63.0 for ages 25 to 29 (Figure 6). Moreover, the estimated numbers of persons diagnosed with thyroid cancer in 2000 were 0, 20, 89, 335, 820, and 1222, respectively.

Based on incidence data collected from 1975 through 2000 in the U.S., approximately 2,400 persons between 19 and 29 years of age had a diagnosis of thyroid cancer. More than half these patients were 25 to 29 years of age. Over this same period, more than 350 older adolescents in the 5 to 19 year age group had a diagnosis of thyroid cancer. (4)

The estimated incidence rates of thyroid cancer in year 1975 through 2000 per million in persons younger than age 44 years, was 0 for age <5 years, to 78% in patients age 40 to 44 years. (Figure 6).

The mortality rate of thyroid cancer increased above the age of 10 years, and continued to rise as a function of age.

It is difficult to dismiss the effect of age on the outcome of papillary and follicular thyroid cancer, including that of prepubertal, pubertal and adolescent patients.

The mortality rate of thyroid cancer increased at greater than 10 years of age and continued to rise as a function of age (Figure 7). Mortality from thyroid cancer has not declined in the 15-

to 29-year age group during the past quarter century, probably because of the high survival rates (1).

It is difficult to dismiss the effect of age on the outcome of PTC.
